AB Animals have been domesticated and kept as a source of milk for tens of thousands of years. When humans keep animals for their ability to produce milk, the animals are usually kept in confined spaces. As a result of this confinement the animals are exposed to high levels of urine and fecal matter which originated with the animals which are being kept. This exposure contaminates the animal and in particular the udder and teats of the animal, with bacteria. In the milking process this bacteria can further contaminate the milk which is destined for human consumption. The bacteria can further cause mastitis in the bovine. The above set forth problems are eliminated in the subject invention wherein the udder and teat areas of the bovine are sanitized with a solution of trichloromelamine.

AB Nitrogen-rich carbon nitride (CN x , x >= 1) network materials have been produced as disordered structures by a variety of precursor-based methods, many that involve solid-state thermolysis at or above 500 degrees C. One popular precursor building block is the triazine unit (C 3N 3), and most postulated amorphous CN x network structures are based on cross-linked triazine units. Since hydrogen is most often observed in the product, these materials are usually more appropriately described as CN x H y materials. Results from recent carbon nitride studies using larger conjugated heptazine (C 6N 7) precursors and from rigorous structural investigations of triazine to heptazine thermal conversion processes have prompted a reexamination of likely local structures present in amorphous carbon nitride networks formed by triazine thermolysis reactions. In the present study, the formation and local structure of a CN x H y material formed via the rapid and exothermic decomposition of a reactive triazine precursor, C 3N 3(NHCl) 3, was examined by byproduct gas mass spectrometry, NMR and IR spectroscopy, base hydrolysis, and crystallographic analysis. The combined results clearly indicate that the moderate-temperature (approximately 400 degrees C) self-sustaining decomposition of trichloromelamine results in ring fragmentation and reorganization into a CN x H y product that contains predominantly larger heptazine-like structural building blocks. These results may have applicability to many other disordered carbon nitride materials that are formed via triazine thermolysis. It also provides clearer and more accurate structural guidance in the use of these carbon nitrides as photoactive materials or coordination supports for metal and nonmetal species.

AB This invention deals with a process for treating and sanitizing animal habitats. In addition to sanitizing the habitat the production of ammonia and odor from fecal matter and urine is inhibited or terminated. In the process an animal habitat is cleaned and subsequently treated with trichloromelamine (TCM). The TCM may be applied by spraying the habitat with a solution of TCM, by dusting the habitat with powdered TCM or by treating bedding/litter with TCM. This process produces healthier animals and as such the productivity of a given grow out is increased. The process of this invention is particularly suited to animal habitats which are used to raise batches of hogs, cattle, turkeys and chickens on a continuous basis.

AB Background: Outbreaks of pathogenic microbial infections associated with the consumption of flesh produce have occurred with increased frequency in recent years. This study was undertaken to determine the efficacy of Sodium hypochlorite (NaOCl), Trichloro-s-triazinetriene (TST), and Trichloromelamine (TCM), commonly used disinfectants, in inactivating viral (MS2) and bacterial (Escherichia coli) indicators, seeded onto wash water produce. Methods: Each microbial challenge consisted of 2L of water containing 8log10 bacterial CFU/mL, and 7log10 viral UFP/mL treated with 100, 200, and 300 mg/L of total chlorine with modified turbidity (2, 100, and 200 NTU). Water samples were taken following two minutes periods of contact with chlorine-based products and assayed for the particular microbial indicator. Results: TST and NaOCl Were found to effectively inactivate greater than 99.99% and 99.99% for bacterial and viral indicators, respectively. The highest inactivation

rate was observed when the turbidity was low. TCM did not show effective results when compared with the TST and NaOCl. There were no statistical differences between TST and NaOCl effectiveness. Conclusion: These findings suggest that lowering the turbidity concentration on water may reduce the interference of the disinfectants activity of chlorine-based products and therefore, may be practical approach to significantly reduce viral and bacterial pathogens from the produce wash water.

AB A series of field tests were made comparing the beer glass sanitizing effect of trichloro-melamine, chloramine T, a quaternary ammonium compound, and hypo-chlorite. When used alone, trichloromelamine and chloramine T are not satisfactory as beer glass sanitizers, particularly if a 2 compartment sink is being used. In general, better results were obtained when a 3 compartment sink was used. Quaternary ammonium compounds are not ideal beer glass sanitizing agents since they may have an adverse effect on beer foam retention. The most effective sanitizer tested was hypochlorite, which also has a disadvantage in that it leaves an objectionable chlorine odor on the beer glass. The major source of general beer glass contamination was the equipment for washing the beer glass. Therefore, by using a detergent sanitizer in the 1st tank of the glass washing sinks, as well as a sanitizer in the last tank, much more satisfactory sanitizing results can be obtained, and the subsequent possibility of carrying pathogens through the solution is greatly reduced.

AB A new facility was designed to hold 1.8 million birds in 10 houses; chickens were placed in five of the houses, and the remaining five houses were under construction when this outbreak occurred. An increase in mortality was reported in five houses; however, mortality in house 7 was quite high. Well-fleshed birds were suddenly found dead without a significant drop in egg production. The middle and distal intestines were distended with gas, congested, thin walled, atonic, and bluish or pale in color with sloughed mucosa in some places. Necrotic enteritis was diagnosed as the cause of increased mortality. The ingesta in the crop occasionally contained flies. The 4-wk mortality in house 7 was 6.55% with a loss of 10,898 chickens. The 4-wk mortality rate in the other houses ranged from 0.54% to 1.98%. The houses affected with necrotic enteritis were treated for coccidiosis with amprolium because low numbers of the oocysts were present in the intestinal specimens of some of the chickens. Household bleach was added to the water at a dilution of one part bleach to 1040 parts water to control bacterial contamination. The fly (*Musca domestica*) population was out of control. *Clostridium perfringens* was isolated from the alcohol-washed macerated flies caught from houses 4 and 7. Dead flies were often seen in the feed troughs. The chickens may possibly have had *C. perfringens* infection as a result of consumption of dead flies or their secretions/excretions. The alcohol-washed, macerated, clarified fly extract from the affected houses caused death in 11 inoculated mice and paralysis in one mouse. Similarly, illness and mortality were present in four mice inoculated with clarified intestinal contents. The bacterium isolated on anaerobic culture was identified as *C. perfringens* by polymerase chain reaction. The disease was brought under control after straw was added and mixed in with the litter. As a result, the litter temperature increased, causing a decrease in the fly population. This study suggests that flies in the poultry houses acted as mechanical transmitters of *C. perfringens* and that the development of necrotic enteritis was by ingestion of bacteria present in the flies and their secretions/excretions.

AB We ran a controlled intervention trial to assess whether the risk of a broiler flock becoming infected with Campylobacter could be reduced by biosecurity measures. These were a standard method of cleansing and disinfecting the poultry house prior to stocking, and a standard hygiene protocol followed by all personnel who entered the study house during the flock's life. Thirty-nine flocks were allocated to intervention or control groups in a ratio of 1:2. Intervention flocks were asked to follow the specified biosecurity measures; all flocks were monitored weekly for Campylobacter infection. Analysis of infection at 42 days of age and over the life of the flock showed that the risk of thermophilic Campylobacter infection of broilers was reduced by over 50% in intervention flocks. Parts of the intervention identified as significant in the univariable analysis included twice weekly replenishment of boot dip disinfectant; potential independent risk factors identified included the location of ventilation fans and daily sanitisation of the water supply. The non-random allocation of 10 flocks to the control group may have introduced some study bias (the effect of which is discussed in the paper).

AB Three broiler breeder houses on three different sites were sampled before and after cleansing and disinfection. None of the farms achieved total elimination of *Salmonella enteritidis* from the poultry house environment but substantial improvements were seen when errors in the cleansing and disinfection protocol in the first house had been corrected. Fundamental errors such as over-dilution and inconsistent application of disinfectants were observed despite supervision of the process by technical advisors. In each of the three poultry units failure to eliminate a mouse population that was infected with *S. enteritidis* was likely to be the most important hazard for the next flock.

AB 1. Studies on the survival of *Salmonella enteritidis* in poultry units and food were carried out over a two-year period. 2. The organism persisted for at least one year in an empty trial house at the laboratory in which naturally-infected broiler breeder birds had previously been housed. A similar survival period was seen in a building which had housed an infected layer breeder flock, although infection was not detected in a subsequent pullet flock. 3. *Salmonella enteritidis* was also frequently found surviving outside poultry houses in small

pockets of litter and fan dust which had been left after cleansing and disinfection of the site. On some poultry units *S. enteritidis* was also found in wild bird droppings. 4. *Salmonella* contamination appeared to persist preferentially in association with dust particles swept from the floor and in food troughs and *S. enteritidis* survived at least 26 months in artificially contaminated poultry food.

AB A study of the dissemination of *Salmonella enteritidis* in the poultry breeder industry in the UK showed that the choice of sites for sampling the environment of occupied houses and empty houses which had been disinfected after depopulation had a significant influence on the outcome. Increased isolation rates could be achieved by sampling nest box floors and dust in open slave feed hoppers in occupied poultry houses. Nest box floors were the most sensitive sites for detection of residual environmental contamination in poultry houses where enrofloxacin treatment had been used. Floor sweepings, nest box floors, slave feed hoppers, hydrated wall fabric junctions and high beams and pipes were the most sensitive sample sites in cleansed and disinfected poultry houses. The use of universal disinfectant neutralisers gave good results in laboratory trials but appeared to reduce the isolation rate from field samples.

- AB Poultry laying flocks can become infected with *Salmonella enteritidis* by several routes. In this study a model is presented of the cumulative infection curve of *S. enteritidis* in laying flocks. Based on this model and practical results the contribution of different routes to the infection can be estimated providing a basis for an effective intervention strategy. For illustration, the cumulative infection curve of *S. enteritidis* in Dutch laying flocks is analysed. This curve shows a low level of infection at the start of the laying period which indicates that the contribution of the vertical infection route (from infected breeding flocks to progeny) is small. The course of the infection curve indicates that there is a high probability of infection in the first part of the laying period. The result suggests that the laying flocks become infected mainly from the farm environment including not properly cleaned and disinfected poultry houses and infected vermin present on the farm. As a consequence, intervention in The Netherlands should be directed to trace *S. enteritidis*-contaminated laying farms and eradicate the contamination.

- AB Good hygiene practices are essential in livestock production. Likewise hygienic production and storage of hatching eggs contribute to improve hatchability and to obtain healthier fowls. This study was designed to compare three methods of disinfection commonly used in poultry houses: fumigation with formaldehyde, pulverization of an iodophore and synthetic phenols. By washing eggs in sterile bags to determine the bacterial contamination on shells, the best results were obtained with formaldehyde, and the smallest bacterial decrease with the iodophore.

AB Four commercial disinfectants used in poultry house sanitation procedures were evaluated for efficacy using a specialized petri dish (Rodac plate) for contact sampling. The samples were taken from a variety of surface materials commonly found in poultry rearing facilities. Two media were used, one for bacteria and one for mold. Predisinfection samples were taken following removal of chickens and litter. Postdisinfection samples were taken 4 hr after room treatment with a high pressure spray apparatus. The most effective disinfectant for reducing bacteria colony counts was a product that contained glutaraldehyde. The other products, ranking in order of efficacy for bacteria, contained cresylic acid, iodophors, and a combination of quaternary ammonium compound and formaldehyde. The most effective disinfectant for reducing mold colony counts was the product containing cresylic acid. The other products, ranking in order of efficacy for mold, contained iodophors, the combination of quaternary ammonium compound and formaldehyde, and glutaraldehyde. The most effective overall disinfectant was the cresylic acid product.

AB The industrial animal-breeding complex is characterized as an ecotechnical system the function of which is determined by the action of antropogenic factors. It has been demonstrated that up to now the stress of antropogenic activity has been laid on the optimization of the abiotic factors. The control and optimization of the biotic factors has constituted a problem for industrial poultry breeding, especially important being the microbial content of air. Investigations have shown that with the industrial raising of birds air microbism has assumed the importance of a factor that lowers the effectiveness of the technologies applied. The factors have been discovered that govern the extent of microbial contamination of air. Results of experiments in productional poultry houses and climatic chambers have led to the offer of measures aimed at limiting the microbial contamination of air in the industrial raising of birds.

AB Campylobacter organisms are present in the environment of the farm and it is accepted that the chance of infection transferring to chickens is very high. Sources of infection may include any of the standard requirements for poultry such as feed, water and litter. Any form of human intervention as a result of routine animal husbandry requirements may also introduce infection. It has been shown that on some farms it is possible to delay infection by various improvements to bio-security arrangements. The use of dedicated wellington boots for each poultry house and the regular use of foot dips were found to be important factors. The daily use of water sanitiser was also important in delaying the onset of infection. The efficiency of cleaning and disinfection and the construction of the buildings were less significant factors. If flocks were thinned, which involves entry by catching crews and equipment, the risk of infection was dramatically increased. After 42 d of age, the likelihood of infection was also much greater. The effectiveness of these intervention procedures applied in one integrated poultry company are described. Generally, it was felt that even the most stringent bio-security measures applied conscientiously would not be able to prevent infection occurring. Once infection has entered the house, all birds become Campylobacter carriers very quickly. A pen trial was set up to investigate this and the results are described.

AB Various micro organisms were exposed to bromomethane (MeBr) gas at concentrations of 20-40 mg/l for 20 hr at 25°. A significant reduction was obtained in the number of viable bacteria and *Aspergillus fumigatus* spores, both in the dry form and in semifluid feces, but no reduction was detected either in dried *Bacillus subtilis* spores or in one of the bacteriophages tested. The investigation indicates that MeBr is less effective against certain viruses, bacteria and fungi than against coccidial oocysts. The results suggest that fumigation of commercial poultry houses with these concentrations of MeBr may not, in all circumstances, provide the overall reduction of poultry pathogens desired.

AB A selection of commercially available disinfectants, sanitizers and water sanitizers based on iodophor, quaternary ammonium compounds

(QACs) and phenolic compounds were tested for their activity against a phage type 4 strain of *Salmonella* serotype Enteritidis in the presence of a variety of organic materials. In general the phenolic preparations were the most effective followed by the QACs and the iodophors. They were all inactivated to different degrees by chick fluff, chicken faeces, feed and wood shavings. The inactivation was greatest when *Salmonella* organisms were pre-dried in feed. Under these conditions formaldehyde and glutaraldehyde were still active. There was some evidence that induced resistance to stress conditions including culture at 42 degree C and anaerobic culture increased resistance to one of the water sanitizers.

AB In 12 disinfected stalls of five breeding farms, 450 samples were tested for the presence of *Salmonellae*. Of the 450 samples 5 were found positive (Table 1). In three cases, a posterior rodent excrement spoilage, in one case the floor and in another case a clumpy spoilage were found to be *Salmonella* positive. *Salmonella infantis* isolated from the rodent excreta failed to play a role in a later *Salmonella* carrier status of the flock (*S. hadar*). *Salmonella* species isolated from the clumpy spoilage and floor proved to be the same serotype that was isolated from the flock set later on (Table 3), however the possibility of the vertical infection could not be ruled out in either of the cases. The tracer organism used for controlling the efficacy of the disinfection (*E. coli*) was found in 51 of the 450 samples collected (11.3%) which suggested that the typical bacterial reservoirs are the floor, the mounted poultry house equipment and rodent excreta (Table 2).

AB The present investigation was undertaken to evaluate the viricidal

activity of the disinfectant VIREX (1% solution) against NDV and IBDV. Birds from NDV contaminated premises remained healthy when they were introduced following disinfection whereas, birds in untreated cages died of ND. In IBDV contaminated and disinfected premises the bursae from the birds were AGPT negative for IBDV while in case of untreated group they were positive. Thus the study infers that the disinfectant VIREX could be used as one per cent solution for the disinfection of poultry houses against NDV and IBDV.

AB The effect of microaerosolized H-2O-2 on bacterial and viral poultry pathogens was investigated. Bacterial cultures and viruses were dried on sterile glass Petri dishes and subjected to direct and indirect 5% (H-2O-2) microaerosol mist. In the trials using *Escherichia coli* and *Staphylococcus aureus*, there was complete inactivation following exposure to H-2O-2. Using *Salmonella typhimurium*, indirect exposure resulted in only partial inactivation whereas direct exposure to H-2O-2 gave complete inactivation. For the viruses studied, 5% H-2O-2 microaerosol mist completely inactivated infectious laryngotracheitis virus. Newcastle disease virus, infectious bronchitis virus, and avian influenza virus showed reduced infectivity but were not completely inactivated. Avian reovirus susceptibility varied with the method of exposure and infectious bursal disease virus was highly resistant. The use of 10% H-2O-2 mist, however, resulted in total inactivation of infectious bursal disease virus. The effect of 10% H-2O-2 on equipment and selected materials representative of a hatchery or poultry house was investigated. A solar cell calculator, a thermostat containing a microswitch, and samples of uncoated steel, galvanized steel, and uncoated aluminum were subjected to 10 fumigation cycles. No damage was detected in the calculator and the thermostat. Both the aluminum did not show signs of oxidation.

AB Over 3 mo. from April-July, 1983, 3 C. jejuni [C. fetus ssp. jejuni] survey studies were done at 4 chicken ranches in northern California. In survey 1, 29 of 200 (14.5%) total cloacal swab and dropping samples collected from the 20 occupied houses on the 4 ranches were positive for C. jejuni. Positive samples were from 2 of the 4 ranches. On 1 of these ranches, both occupied houses were positive. On the other ranch, only 1 of 6 houses was positive. Follow-up feed, water, litter and dropping samples were collected from 3 houses on this latter ranch during survey 2. Again, positive samples were from only 1 house, with 26 of 30 (86.7%) droppings positive for C. jejuni and 3 of 20 (15%) water samples positive. No feed or litter samples were positive. During survey 3, cloacal swabs or bird dropping samples were collected from 2 houses on each of 3 ranches of approximately weekly intervals from the time of arrival of new flocks of chickens. All 6 houses ultimately became positive. The 1st positive samples were collected from 1 house when chickens in that house were 12 days old. This house had contained C. jejuni-positive chickens during survey 1, had old litter and had not been very thoroughly cleaned and disinfected. First positive samples in each of the other 5 houses were collected when chickens were 40-46 days old. Two of these houses had previously been positive for C. jejuni but had old litter replaced with new and had been thoroughly cleaned and disinfected. The 3 other houses had been thoroughly cleaned and disinfected. The 3 other houses had been negative for C. jejuni during survey 1. Two of these houses had new litter and had been well cleaned. The other house contained old litter and had not been well cleaned. When each house became positive, virtually all samples from that house were positive within a week indicating that C. jejuni likely spreads rapidly among birds in the house. [Poultry has been incriminated in foodborne Campylobacter enteritis.].

AB Experiments were performed to examine the effect of long term disinfection by using a rotary spray system without removing the birds on the sanitary environment in windowless floor-type poultry houses. The disinfectant apparently was effective in controlling bacterial growth and did not have any adverse effects on the chickens.

AB In the past 5 years (1960-1965) different organs of 1163 dead fowls (hens, turkeys, geese, ducks) were examined bacteriologically. Escherichia coli was isolated in most cases 39.30% (1964)-58.33% (1960). Almost as a regular companion of E. coli was Staphylococcus albus: 8-33% (1960)-28.97%(1963). Mycoplasma were also frequently found: 17.61%(1964). In a great number of dead fowls all 3 groups of bacteria were simultaneously isolated. Among other bacteria, Bacillus pyocyaneus [Pseudomonas aeruginosa] was mainly identified in water birds. The occurrence of aspergillosis was connected with contaminated feed and badly disinfected poultry-houses, as Aspergillus was

isolated just in those cases when the feed was contaminated with fungi.

AB This is an extensive discussion of diseases of chickens and their control, which has for its principal subdivisions, types of poultry disease, breeding for disease resistance, types of measures for the control of infectious diseases and parasites, sanitary considerations in the construction, equipment, and care of poultry houses, sanitation of poultry yards, disinfection and disinfectants, management practices in preventing and controlling transmissible diseases, infectious diseases, nutritional diseases, nonspecific diseases, cannibalism, external parasites and internal parasites. A major portion of the material presented is based upon work done at the Calif. Agric. Exp. Sta., but information obtained from the work of others has been freely used. The diseases and parasites which are of greatest economic importance in Calif. are discussed in detail. Included is a chapter on avian pneumoencephalitis, a newly (1942) identified virus disease of chickens and turkeys, in which both the respiratory organs and the central nervous system are involved. The virus is distinct from any previously known to be present in the U. S.

AB The resistance of coccidial oocysts to the blowlamp flame is approx. the same as that of Chromobacterium prodigiosum. Because of the ease and certainty with which the presence of living bacteria could be determined by cultural methods this organism was used as an index of the efficiency of disinfection from coccidia by the blowlamp. Exposure to the blowlamp flame for a second proved sufficient to kill both C. prodigiosum and coccidial oocysts, but approx. 1/2 second on rough surfaces occasionally failed to kill both of these organisms. It was found to be necessary to spend more than 20 sec. in naming 1 sq. foot of clean rough board in order to kill all C. prodigiosum that had been painted on it. C. prodigiosum spread in a thin film of feces on a sq. foot of rough board survived 70 sec. flaming. It is necessary to spend more than 100 sec. in flaming a sq. foot of smooth wood, rough wood, zinc, or asbestos, if damp,

in order to kill all *C. prodigiosum* present. ABSTRACT AUTHORS: W. G. Venzke

AB This is a summary of information on infectious bronchitis, prevalent on poultry farms in California, based on a review of the literature and work conducted at the Petaluma poultry disease laboratory. It has been observed in chickens, turkeys, pigeons and ducks, and in wild quail, sparrows and blackbirds; it is entirely distinct from chicken pox. The causative agent has not been identified; its presence can be demonstrated in the tracheal exudate of affected fowls, but not in other organs. The disease is thought to be caused by a filterable virus, but attempts to reproduce the disease by inoculation with sterile filtrates proved unsuccessful. Recovered fowls appeared to have an immunity sufficient to protect them from infection for at least a year. Attempts to immunize fowls against the disease by subcutaneous injection of tracheal exudate which had been treated with phenol, formalin, glycerin or chloroform, or by intratracheal injection of minute amounts of virulent material, were unsuccessful. Treatment of diseased fowls by intratracheal injection of antiseptics not only failed to benefit the fowls, but in many instances hastened their death. Vaporizing coal tar disinfectant in poultry houses occupied by an infected flock did not check the spread of the disease or reduce the mortality. ABSTRACT AUTHORS: W. A. Hooker (courtesy Exp. Sta. Rec)
